43 **Abstract**

44

45 Thermal analysis of aerosol size distributions provided size resolved volatility up
46 to temperatures of 400°C during extensive flights over North America (NA) for the
47 INTEX/ICARTT experiment in summer 2004. Biomass burning and pollution plumes
48 identified from trace gas measurements were evaluated for their aerosol physio-chemical
49 and optical signatures. Fast measurements of soluble ionic mass and refractory black
50 carbon (BC) mass, inferred from light-absorption, were combined with volatility to
51 identify residual volatile organic carbon (VolatileOC) and refractory organic carbon,
52 RefractoryOC. This approach characterized distinct constituent mass fractions present in
53 biomass burning and pollution plumes. The “non-plume” regional haze exhibited
54 statistical properties reflecting both plume types but was dominated by pollution
55 characteristics near the surface and biomass burning aloft.

56 VolatileOC included most water-soluble organic carbon. RefractoryOC
57 dominated the enhanced shortwave absorption in plumes from Alaskan and Canadian
58 forest fires. The RefractoryOC mass absorption efficiency was about $0.51 \text{ m}^2\text{g}^{-1}$ at 470
59 nm and $0.16 \text{ m}^2\text{g}^{-1}$ at 530nm. Biomass burning, pollution and dust aerosol could be
60 stratified by their combined spectral scattering and absorption properties. Concurrent
61 measurements of the humidity dependence of scattering [f(RH)] found the VolatileOC
62 component to be only weakly hygroscopic resulting in a general decrease of overall
63 f(RH) with increasing OC mass fractions. Under ambient humidity conditions, the
64 systematic relations between physio-chemical properties and f(RH) lead to a reduced
65 variability in the single scattering albedo and a simple dependency on the absorption per
66 unit dry mass for these plume types that may be used to challenge modeled optical
67 properties.
68

69 1.0 Introduction

70

71 The importance of aerosol physical, chemical and optical properties and their role
72 in regional and global climate forcing is well recognized. Yet there remains considerable
73 uncertainty about the contribution of both natural and anthropogenic aerosols to their
74 overall radiative effects [Bates *et al.*, 2006]. Some of this uncertainty is due to the
75 complex and varied properties of organic aerosols and more information on the
76 contribution of OC to aerosol physio-chemistry is needed in order to better model their
77 optical properties [Kanakidou *et al.*, 2004]. Properties of key significance from a climate
78 and radiative perspective are the size distribution, light scattering and light absorbing
79 properties, and the hygroscopic properties that control the uptake of water, ambient
80 aerosol optical properties and activation in cloud. The extent to which organic aerosol are
81 internally or externally mixed with other aerosol types is also an important determination.
82 Given the thousands of organic species and their diverse characteristics, a means for
83 generalizing relevant properties is desirable. One commonly identified grouping is the
84 water soluble organic carbon (WSOC) species recently measured aboard research aircraft
85 [Weber *et al.*, 2001]. The remaining water insoluble components can be expected to have
86 physiochemical and optical properties distinct from the WSOC.

87 One optically important characteristic is the particle light absorption coefficient,
88 σ_{ap} . There is a long history of measuring light absorbing carbon (LAC) and black carbon
89 (BC), often associated with soot; and yet significant uncertainties remain and differences
90 exist in fundamental properties like the mass absorption coefficient (MAE) or refractive
91 index and best ways to report them [Bond and Bergstrom, 2006]. The recognition that
92 organic carbon (OC) aerosol can absorb appreciably, particularly at shorter wavelengths
93 [Kirchstetter *et al.*, 2004], has refocused attention on light absorbing properties of this so-
94 called “brown carbon” and the need for multi-wavelength measurements [Andreae and
95 Gelencser, 2006]. Measurements of MAE for OC aerosol from typical sources are rare
96 but provide an important tool for models that carry OC mass and use it to estimate
97 aerosol optical effects.

98 Recently, so called Humic Like Substances (HULIS) have been suggested as a
99 major component of absorbing OC. Humic substances include fulvic acid (water
100 soluble), humic acid (base soluble) and humin (insoluble) components [Graber and
101 Rudich, 2006]. HULIS also includes both water soluble and insoluble fractions.
102 However, most studies have focused upon the water soluble fraction or fulvic acid
103 component and not the humic acid or insoluble humin component that is more absorbing
104 in the shorter wavelengths [Graber and Rudich, 2006]. These authors also note that
105 transformation of OC components and types can occur in the atmosphere over time and
106 considerable uncertainties exist regarding the various sources, transformations and
107 properties of both soluble and insoluble components.

108 The water uptake by aerosol must be quantified to correctly calculate or model
109 optical effects under actual atmospheric conditions. Recent evaluations of aerosol
110 humidity-dependent growth have recognized the influence of OC in suppressing aerosol
111 growth compared to that of common ionic species alone [Quinn *et al.*, 2005]. Although
112 OC may suppress aerosol growth, the presence of WSOC may enhance the nucleating
113 properties of some insoluble aerosols (such as dust) and making them more effective

114 cloud condensation nuclei [Mayol-Bracero *et al.*, 2002b]. Hence, OC properties can
115 influence both the direct and indirect radiative effects of aerosol.

116 Here we demonstrate the application of aerosol volatility, in conjunction with
117 measurements of ions and inferred BC, to establish the volatile and refractory
118 components aerosol OC at 400°C over North America during INTEX-A. An overview of
119 INTEX-A is presented elsewhere [Singh *et al.*, this issue, submitted]. We will
120 demonstrate that the volatile component appears to be dominated by WSOC while the
121 refractory OC is primarily responsible for enhanced absorption at shorter wavelengths
122 relative to BC. This data will be used to establish the MAE for the non-BC component of
123 BB plumes. Statistically robust differences in the mass fractions present in pollution and
124 biomass plumes will be related to their different hygroscopicity as well as spectral
125 signatures associated with their absorbing and scattering properties.
126

127 **2.0 Aircraft Measurements**

128

129 **2.1 Aircraft Inlet Sampling Performance**

130

131 During INTEX-A the University of Hawaii (UH) solid diffuser inlet was used to
132 sample in-situ aerosol size distributions and optical properties aboard the NASA DC-8.
133 Aerosol bulk-chemistry filter samples were measured behind the University of New
134 Hampshire (UNH) solid diffuser inlet. Inlet intercomparisons during the 2003 DC-8 Inlet
135 Comparison Experiment (DICE) demonstrated that the UH and UNH inlets perform
136 nearly identically while sampling both supermicrometer sea salt at high (80-95%) relative
137 humidity and supermicrometer mineral dust in desert environments. Comparisons with
138 ground based instrumentation show that the UH and UNH inlets and transport system
139 pass particles with geometric equivalent diameters (D_g) of 3.0 μm and 2.6 μm (for $\rho=2.6$
140 g cm^{-3}) with better than 50% efficiency [McNaughton *et al.*, submitted 2006]. Because
141 aerosol optical properties are typically dominated by smaller particle sizes the INTEX-A
142 DC-8 aerosol data set can reliably address both the direct and indirect effects of aerosols
143 in the ambient atmospheric environment.
144

145 **2.2 Thermally Resolved Aerosol Size Distributions**

146

147 Before size distributions were measured, the sample air stream was mixed with an
148 equal flow of dessicated filtered air. This technique minimizes size variability due to
149 water uptake and uncertainties associated with refractive index effects. A modified PMS¹
150 laser optical particle counter (OPC) was used to measure the dry (RH < 30%), optically
151 effective aerosol size distribution between 0.1 μm and 10 μm every 3 seconds [Clarke *et al.*
152 *et al.*, 2004]. The OPC is calibrated before during and after deployment using a
153 combination of NIST² traceable polystyrene microspheres (Duke Scientific), silica
154 microspheres, and borosilicate glass microspheres. The He-Ne OPC laser operates at
155 633 nm and detects light scattered by individual particles over 35 – 145 degrees. Since
156 the OPC measures optically effective sizes (D_{oc}) directly it is well suited to modeling

¹ Particle Measurement Systems, Boulder, Colorado

² National Institute of Standards and Technology

157 aerosol optical properties. Total and submicrometer scattering calculations from the size
158 distributions compared to measured scattering values has an r^2 statistics of better than
159 0.95 [Shinozuka *et al.*, submitted 2006].

160 The OPC operates in series with a newly redesigned thermo-optical aerosol
161 discriminator (TOAD). The design is based on [Clarke, 1991] but includes an additional
162 temperature channel at 400°C. During horizontal flight legs the TOAD cycles between
163 temperature channels every 30 seconds. This results in thermo-optical characterization of
164 the optically effective size range every 2 minutes. During vertical profiles the OPC does
165 not cycle between temperatures. At a nominal DC-8 ascent/descent rate of 450 m min⁻¹
166 this results in vertical resolution of statistically-robust individual submicrometer aerosol
167 size distributions over 25 meter intervals. Larger particle sizes require averaging due to
168 lower count statistics.

169 Aerosol chemistry was also measured on filter samples using ion-chromatography
170 as described by Dobb *et al.*. Filter samples were typically exposed for 5-10 min below
171 6km and somewhat longer aloft and generally analyzed within 24 hours. These data are
172 essential to link measured volatility and aerosol chemistry to its optical effects in the
173 atmosphere. This is due to the dependency of light scattering on ambient humidity as a
174 result of the uptake of water by soluble constituents. Such data is required in order to
175 interpret optical measurements (e.g. satellite retrievals) in terms of the chemical
176 components that give rise to them. Understanding this variability requires merging both
177 soluble and insoluble aerosol components with the measured chemistry and the f(RH)
178 measurements described below.

179
180

181 **2.3 Aerosol Optical Properties and f(RH)**

182

183 Total and submicrometer aerosol scattering ($\sigma_{sp, tot}$, $\sigma_{sp, sub}$) is measured using two
184 TSI model 3563 3- λ integrating nephelometers [Anderson *et al.*, 1996; Heintzenberg and
185 Charlson, 1996] corrected according to [Anderson and Ogren, 1998]. The
186 submicrometer TSI nephelometer employs a 1- μ m aerodynamic impactor maintained at
187 30 lpm using an Alicat Scientific volumetric flow controller. Sample air residence time
188 inside the nephelometers is less than 10 seconds and the instrument relative humidity
189 (RH) is typically less than 30%. Two single-wavelength ($\lambda = 540$ nm) Radiance
190 Research model M903 nephelometers are operated in parallel providing a direct
191 measurement of the increase in light scattering as a function of relative humidity, f(RH)
192 [Howell *et al.*, 2006a]. The humidified nephelometer is operated at 80% RH while the
193 dry nephelometer RH was maintained below 40%. Temperature and relative humidity
194 were measured using Vaisala RH & T sensors³. These sensors were embedded directly in
195 the RRNeph sample outlet without their protective sheath to improve response time. This
196 measurement of f(RH) provides a two point measurement that can be fit using to express
197 the growth response, γ , of the scattering, σ , using Eqn. 1.

During INTEX-A a prototype 3- λ Radiance Research particle soot absorption photometer (PSAP) was provided by Dr. David Covert (University of Washington) to measure aerosol light absorption at 470, 530, 660 nm wavelengths. The data shown here are based upon calibration and corrections for this new instrument reported elsewhere [Virkkula *et al.*, 2005]. At the relatively high single scatter albedos (SSA) and low PSAP filter loadings seen in INTEX-A, the results are roughly 25% lower than the correction scheme used in the past for single wavelength PSAP's [Bond *et al.*, 1999]. The reasons for the discrepancy are not clear; [Virkkula *et al.*, 2005] suggest that their use of fresh soot from a flame rather than nigrosin dye may be responsible. Neither particle type is representative of the atmospheric aerosol we sampled, and [Virkkula *et al.*, 2005] did not use particles with SSA>0.9. The high aerosol concentrations, low SSA, rapid filter loading and resulting low filter transmittance values may have also contributed. Additionally, the light source and optical path in the prototype instrument used by Virkkula was significantly different than the unit used in INTEX-A. Calibration results since with a newer instrument do not support the logarithmic transform and are closer value to the algorithm of Bond *et al.* 1999 (personal correspondence, D. Covert, unpublished results). Consequently, we believe the absorption values presented here may be a lower limit but this will have little effect on the observations discussed here.

240

Plumes from western North America biomass burning sources can evolve and mix with continental pollution sources to contribute to regional pollution outflow from North America [Li *et al.*, 2005]. The properties of regional pollution can be expected to reflect the input from both biomass and continental plume types along with other more diffuse sources. Repeated encounters with diverse plumes aloft during INTEX-A [Singh *et al.*, this issue, submitted] provide a statistical characterization of the chemistry, physics and optical properties of these aerosol plume types. Here we characterize all data in terms of biomass burning (BB) plumes and pollution (P) plumes that stand out against a regional background. These plumes have been identified based upon trace gas concentrations. An air mass characterization was carried out for 84 INTEX-A "plumes" as flight leg average values covering a total of ~ 24 hours of flight time. These plumes are characterized by signature species (e.g., CO, O₃, NO₂, SO₂, HCN, C₃H₈, and C₂H₂) that exhibited elevated levels over 95th percentile for the altitude level of the observation.

We began the screening procedure by first establishing the background concentrations of the signature species by dividing the measurements into 1-km altitude bins and creating vertical profiles of each species. A plume encounter was identified when one of the tracer species exceeded the 95th percentile of the measured values (with respect to altitude). Also, in order to facilitate the classification, 10-day back trajectories

241 were analyzed for each plume, as well as secondary tracer species. Biomass burning
242 plumes were associated with high concentrations of the signature species HCN, CO, and
243 ethyne, and elevated levels of the secondary species: absorption, CH₃CN, and K⁺.
244 Pollution plumes were associated with high concentrations of the species: O₃, CO,
245 alkanes, SO₂, NMHC, and ultrafine condensation nuclei (> 3 nm). As defined, some of
246 these plumes will inevitably reflect a mix of plume and non-plume air encountered over a
247 given leg. These are available on the NASA INTEX-A archive (ftp-
248 air.larc.nasa.gov/pub/INTEXA/MERGES/DC8/1_MINUTE/).

249 The spatial distribution of these plumes is shown as circles for our 60s data
250 collected over eastern NA superimposed on the flight tracks (thin lines, **Figure 1a**). The
251 size of the circles are proportional to the 60 second average scattering values. These
252 plumes are also evident in flight-leg average values averaged over 250 m altitude bins in
253 **Figure 1b** and shown as horizontal lines superimposed upon the grey “non-plume”
254 background. Below 1 km the plumes were exclusively identified as pollution. The total
255 number of BB and P plumes are similar in the 1-3 km altitude, a region that includes most
256 active exchange between the boundary layer and free troposphere. From 3-7 km most
257 plumes identified by the 95th percentile exceedences are biomass burning plumes
258 identified as originating in Alaska and western Canada. At higher altitudes, isolated
259 dilute plumes of either type are present which include deep convection over the continent
260 in summer and some intrusions of stratospheric air.
261

262 **4.0 Thermal Analysis and Aerosol Carbon**

263
264 Our thermal treatment produces large changes in the aerosol volume distribution
265 and providing information on the volatility of the aerosol components, state of mixing
266 and the residual refractory component remaining at the highest temperature used. High
267 temperature refractory materials include dust, fly ash, black carbon (BC, soot) and
268 organic species stable at high temperatures. It is now clear that some OC can evolve over
269 a range of temperatures that can overlap those at which BC evolves [*Andreae and*
270 *Gelencser, 2006; Bond and Bergstrom, 2006; Mayol-Bracero et al., 2002b*]. BC may
271 also evolve at different temperatures below 450°C depending upon origin, state of mixing
272 and aging etc. Moreover these papers (and references therein) discuss at length how
273 some of the aerosol OC is also light absorbing, in addition to aerosol BC, prompting the
274 suggested term light absorbing carbon (LAC) for the possible mixtures of these
275 components. Laboratory samples of two of these absorbing OC components (lignin and
276 humic acid) were shown to have multiple peaked structure in their thermal evolution up
277 to temperatures of 700°C [*Andreae and Gelencser, 2006*]. Enhanced light absorption at
278 shorter wavelengths is characteristic of these and other HULIS such as those observed in
279 biomass-burning aerosols over the Amazon [*Hoffer et al., 2005*].

280 Our measurements use these volatility and absorption properties to characterize
281 BC and OC and its influence upon aerosol measured over North America during INTEX-
282 A. In order to clarify our approach we employ the observations shown in **Figure 2** as
283 reconstructed from thermograms shown in the paper by Kirschtetter et al. [*Kirchstetter et*
284 *al., 2004*] and Mayol-Bracero et al. [*Mayol-Bracero et al., 2002a*]. Kirchstetter et al.
285 show the thermally evolved CO₂ before and after extraction of the samples using acetone

286 to remove acetone soluble OC. Here we plot the difference (the evolved OC soluble in
287 acetone) measured as thermally evolved CO₂ (relative units) in an oxidizing atmosphere
288 for a sample dominated by biomass burning from South Africa in **Figure 2a** and by
289 aerosol dominated by road-tunnel diesel exhaust in **Figure 2b**. Gaussian fits to the
290 curves associated with the light absorbing BC have been added to reflect the apparent
291 contributions from this component. The peak near 400-500°C in diesel exhaust cases is
292 primarily associated with the light absorbing BC. Diesel soot is a common LAC that is
293 high in BC and it has been found to combust over a narrow temperature range between
294 470°C and 510°C [Wittmaack, 2005]. This is consistent with the main peak for pollution
295 in **Figure 1**. However, there is evidence that mixing with other inorganic species and
296 aerosol aging can catalyze oxidation [Andreae and Gelencser, 2006] and shift thermal
297 evolution to lower temperatures by as much as 100°C [Novakov and Corrigan, 1995] in
298 response to the presence of metals such as Na⁺ or K⁺.

299 The BC peak in **Figure 2a** is suggested here based upon the most distinct peak
300 location but differencing the acetone treated and untreated data peak temperatures may
301 generate some peaks at temperatures that can be uncertain for the reasons just discussed.
302 Most acid soluble OC typically evolves below 400°C but it does have a “tail” that extends
303 as high as 600°C. This behavior is also evident for mixed pollution and biomass burning
304 aerosol collected over the Indian Ocean [Mayol-Bracero *et al.*, 2002a] using a similar
305 technique (**Figure 2c**) and Amazonia [Mayol-Bracero *et al.*, 2002b]. Here the light
306 absorbing BC peak was identified during thermal evolution and is highlighted as a
307 darkened lognormal about 500°C. The evolved carbon peaks below 400°C are non-
308 absorbing particulate OC.

309 These examples in **Figure 2** should only be taken as broadly illustrative of
310 possible OC and BC thermal volatility and its variability. In general there can be
311 multiple peaks of non absorbing particulate OC volatile below 400°C we will call
312 VolatileOC. Above 400°C light absorbing BC evolves but may do so at different
313 temperatures that can depend upon sources, composition, state of mixing, trace metals
314 etc. There is also clearly a less absorbing RefractoryOC component that often evolves at
315 temperatures above 400°C and in a similar temperature range as absorbing BC and is
316 partially soluble in acetone.

317

318 **5.0 Aerosol Composition and Thermal Volatility**

319

320 The vertical lines shown in **Figure 2** at 150°C, 360°C and 400°C include
321 temperatures we have previously used in our thermal analysis of volatility [Clarke *et al.*,
322 2004]. Our size-resolved thermal analysis was originally developed for clean marine
323 regions where sea-salt, sulfates and low mass fractions (ca. 15%) of organic components
324 typically characterize the aerosol [Clarke, 1991]. More recently and using fast
325 measurements of soluble ions [Weber *et al.*, 2001] we were able to identify the
326 contribution of volatile ions to our total volatile aerosol assessment [Clarke *et al.*, 2004;
327 Howell *et al.*, 2006b]. The 400°C temperature was added for INTEX-A to better remove
328 the OC stable at higher temperatures but without removing the BC, as indicated in the
329 prior discussion. Consequently, in this paper the VolatileOC is the inferred OC
330 volatilized at 400°C and the RefractoryOC is the inferred OC remaining at 400°C.

331 The differences in gas phase properties that allowed identification of BB and P
332 plumes (**Figure 1**) is also reflected in differences in aerosol properties including their
333 volatility. **Figure 3** shows examples of the effect of thermal heating on the size
334 distributions for a representative P and BB plume. These include volume distributions
335 observed at about 40°C, 150°C, 360°C and 400°C. In this paper only the unheated and
336 400°C heated volumes will be used. For the remainder of this publication, aerosol mass
337 fractions derived from the thermally resolved size distributions are based on the
338 following assumptions.

- 339
- 340 • All accumulation mode aerosol is assumed to be internally mixed. This was
341 generally the case as determined using our thermal Tandem Differential Mobility
342 Analyzer (unpublished INTEX-A data) and consistent with our observations in
343 similarly polluted regions after several hours of aging [Clarke *et al.*, 2004].
- 344 • The submicrometer OPC data includes most of the aerosol responsible for light
345 scattering, light absorption, BC (soot) soluble ions, for the INTEX-A experiment
346 with the exception of about 5% of the data when substantial coarse particles are
347 present. We assume the OPC volumes are realistic because light scattering
348 calculated from OPC size distributions was found to reproduce measured light
349 scattering to within about 10% [Shinozuka *et al.*, submitted 2006]
- 350 • The submicrometer aerosol components volatile below 400°C include all the
351 measured soluble ions [Dibb *et al.*, 2003] converted to $\mu\text{g m}^{-3}$ and the volatile
352 organic carbon (VolatileOC). We estimate the mass of VolatileOC by subtracting
353 the volume of the ions from the total volatile volume and assigning a density of
354 1.3 g cm^{-3} for the remaining VolatileOC volume. This is based upon a suggested
355 range of 1.2 to 1.4 g cm^{-3} for organic aerosol [Stelson, 1990; Turpin and Lin,
356 2001] and a reported value of 1.4 g cm^{-3} for biomass smoke [Reid *et al.*, 2005].
357 We made our choice expecting the VolatileOC to be lower than the BC and
358 RefractoryOC in smoke.
- 359 • The aerosol volume (mass) remaining at 400°C includes refractory organic carbon
360 (RefractoryOC) and absorbing black carbon (BC). The BC mass fraction is
361 inferred (InferredBC) based on a nominal mass absorption efficiency (MAE) of
362 $10 \text{ m}^2 \text{g}^{-1}$. We have argued that a more appropriate value is likely to be $7.5 \text{ m}^2 \text{g}^{-1}$
363 [Clarke *et al.*, 2004] and consistent with a recent survey of likely values [Bond
364 and Bergstrom, 2006]. However, we use the higher value here in order to allow
365 for a possible optical enhancement due to other internally mixed components
366 [Fuller *et al.*, 1999]. As we will demonstrate, the mass of this BC component is
367 small and the uncertainty associated with this choice has little effect on the
368 resulting inferred OC discussed in this paper.
- 369 • We use volume based mixing rules with component densities of 1.8 g cm^{-3} for the
370 refractory BC [Fuller *et al.*, 1999]. We are not aware of any density data on
371 RefractoryOC and have arbitrarily used the recent value of 1.5 g cm^{-3} for bulk
372 HULIS [Hoffer *et al.*, 2004] as we expect RefractoryOC density to be greater than
373 VolatileOC but less than BC.
- 374 • We use a representative mean density of ionic components of about 1.75 g cm^{-3}
375 [McMurry *et al.*, 2002; Stelson, 1990]. We also assume any potential interaction
376 between mixed components does not influence their effective density.

- 377 • RefractoryOC volume is computed as the difference between volume remaining at
378 400°C and the volume of inferred BC (i.e. area under the black curve in figure 3
379 less the volume of inferred BC).
380

381 In this manner the total accumulation mode mass is broken down into ionic,
382 VolatileOC, RefractoryOC, and BC mass. If coarse dust or fly ash had been a common
383 contributor to the data then additional procedures could be implemented to extract these
384 components based upon their size distributions [Clarke *et al.*, 2004] but this is not
385 included here. We cannot tell fly ash or submicron dust from RefractoryOC, but we have
386 no reason to believe either was important during INTEX-A. We do not include the
387 possible impact of changes in refractive index upon OPC sizes arising due to volatilizing
388 components here.

389 The results of this procedure for the examples of P and BB size distributions
390 reveal marked differences and are illustrated here as pie charts in **Figure 3**. The inferred
391 P aerosol dry mass is dominated by soluble inorganic ions (79%) with about 16% volatile
392 OC and 4% refractory OC. The estimated BC is only 2% of the mass and supports the
393 argument above that uncertainty in the MAE has little impact on the determination of the
394 other constituents. In the case of BB these inferred mass fractions are quite different.
395 The BB ionic fraction is about a factor of 4 lower than P at 22%. Volatile OC is a factor
396 of 3 higher at 58% and Refractory OC is a factor of 4 higher at 18%. Inferred BC
397 remains a small fraction of the total mass at 3%.

398 This approach is used to evaluate all of the thermally-resolved size data for which
399 corresponding ionic and BC estimates were available on the DC-8. The results of these
400 assessments were then stratified into BB and P categories based upon the trace gas
401 analysis described earlier. In this fashion, statistically representative composition and
402 properties can be constructed for BB, and P plumes as well as the regional data not
403 characterized as plumes. **Figure 4** shows histograms of the mass fractions of ions,
404 Volatile OC, RefractoryOC, Inferred BC and f(RH) for the BB, P and non-plumes cases
405 for INTEX-A. The differences noted for the two plume cases shown in **Figure 3** are
406 consistent with the differences evident in the campaign histograms although there is
407 clearly some variability within each plume class. This reflects both variability present in
408 plume composition and that of the air mass into which the plumes are mixed. The largest
409 differences in BB and P mass fractions is in the ions that dominate the mass fraction of P
410 plumes. VolatileOC and RefractoryOC together dominate BB plumes. The typical values
411 for BB are similar to mass fractions reported for biomass burning in Africa [Haywood *et*
412 *al.*, 2003] of 5%BC, 70%OC and 25% inorganic. Visual inspection of the non-plume
413 histograms suggest BB influences were present in approximately 20% of the data,
414 indicating that pollution was the greatest contributor to regional aerosol properties during
415 INTEX-A.

416 In spite of the large differences in most BB and P mass fractions evident in
417 **Figure 4** the relative components of the carbon mass are less different in BB and P
418 plumes. Both VolatileOC and RefractoryOC can be present in biomass and pollution
419 aerosol but appear much enhanced relative to BC in the former. **Figure 5** provides
420 histograms of mass fractions of the total carbon defined here as the sum of inferred BC
421 mass and volatile OC. The Volatile OC is typically about 90% of Total OC in P vs. about
422 75% in BB plumes. RefractoryOC is about 30% of Total OC in BB plumes; twice the

423 value in typical P plumes. Inferred BC remains a few percent of the carbon in both
424 plumes but is typically a larger fraction of the total refractory mass in P plumes due to the
425 lower Refractory OC in these plumes. However, the lower panels show that the inferred
426 BC in pollution plumes tends to be a larger and much more variable fraction of the
427 refractory mass remaining at 400°C compared Inferred BC in the biomass burning
428 plumes.

429 This characterization of plumes in terms of their inferred OC fractions suggest
430 properties that may be linked to the physiochemical nature of these aerosol types.
431 However, no measurements of organic aerosol components were made aboard the DC-8
432 and the rare comparisons with surface sites were too short and/or in inhomogeneous
433 conditions such that no direct comparison of our volatility with independent
434 measurements of aerosol OC concentrations were possible. However, the NOAA P-3 did
435 have a rapid measurement of water soluble OC (WSOC) [Sullivan *et al.*, 2004] for flights
436 over the eastern US during the same time period [Sullivan *et al.*, submitted 2006]. In this
437 paper the authors plot their measured WSOC for non-biomass burning sources below 2
438 km vs. measured CO. As the DC-8 flew in similar regions and for similar times we can
439 compare our inferred VolatileOC vs. measured CO for comparison to the NOAA-P3
440 WSOC vs. CO plot from Sullivan *et al.* to explore similarities in their behavior.

441 In **Figure 6** we plot our VolatileOC against fast CO measured on the DC-8
442 [Sachse *et al.*, 1987] below 2 km and we include the line fit proposed by Sullivan *et al.*
443 for non-BB data. The fit line has a slope of 0.026 $\mu\text{gC m}^{-3}$ per ppbv and intercept of -2.0
444 $\mu\text{gC m}^{-3}$ with an $r^2=0.54$. In order to be consistent with their approach, in **Figure 6a**
445 only we have adjusted our VolatileOC mass (based upon a 1.3 g cm^{-3}) to values based
446 upon their assumed density of 1.0 g cm^{-3} for WSOC. We note that the scatter in the data,
447 the overall data distribution, the grouping of near zero VolatileOC for CO values over
448 100-150ppbv are virtually identical to the WSOC data as presented in Sullivan *et al.*. We
449 have also added four data points (green stars) to the plot that were reported by these
450 authors (their Table 2) as measurements in BB. Our DC-8 data for P (red), BB (blue) and
451 non-plume cases (grey) clearly show that our BB cases and three of their four stars have a
452 strong and consistent linear relation with CO. These all fall in the upper limit of our data
453 points. The different relation evident for their fourth star was not discussed by the
454 Sullivan *et al.* Also, their data does not show WSOC values measured below about 0.2
455 $\mu\text{gC m}^{-3}$ while our estimates go negative at times with a common deviation of about 0.5
456 $\mu\text{gC m}^{-3}$. This is largely because we are subtracting heated and unheated size
457 distributions that are sampled sequentially and separated by up to 2 minutes (or up to 20
458 km at DC-8 speeds). At low and variable concentrations this can generate negative
459 differences. However, the magnitude of this difference suggests an overall uncertainty in
460 our measurement approach of about $\pm 0.7 \mu\text{gC m}^{-3}$. Even so, the clear similarity of the
461 relationship between WSOC and CO and that of our VolatileOC to CO strongly suggests
462 that our VolatileOC contains most of the WSOC and may be a useful proxy for WSOC.

463 **Figure 6b** shows the result of plotting our Refractory OC against CO for the same
464 data. Refractory OC has a distinct relation to CO for P and BB plumes with about four
465 times as much Refractory OC per CO concentration evident in the latter. Flight legs with
466 encounters of both P and BB plumes (so-called mixed plumes) are elevated relative to P
467 plumes. Because VolatileOC for BB plumes in **Figure 6** appears quantitatively the same
468 as the WSOC in these plumes, this implies the RefractoryOC in BB plumes (**Figure 6b**)

469 is mostly insoluble OC. This suggests less RefractoryOC is soluble for these BB plumes
 470 than found for BB plumes in the Amazon [Mayol-Bracero *et al.*, 2002b]. Given the
 471 relatively small amount of RefractoryOC in P plumes compared to VolatileOC it is not
 472 clear to what extent the RefractoryOC is water soluble.

473 As VolatileOC appears dominated by WSOC and makes up most of the OC we
 474 can explore its relation to variability in γ or $f(\text{RH})$, as indicated in **Figure 4**. In **Figure 7a**
 475 **and 7b** we plot γ vs. the volatile organic carbon fraction and the total ion mass fraction
 476 for the data we have been considering here. γ shows no clear relation to the volatile OC
 477 fraction. Even though VolatileOC is a larger fraction of total mass in BB plumes (**Figure**
 478 **3**) γ is actually lower for these plumes indicating it is not a significant contributor to
 479 $f(\text{RH})$ and hence only weakly hygroscopic. However, γ is strongly related to the ion mass
 480 fraction, the background data and some of the BB data. A plot of γ against the OC
 481 fraction of accumulation mode mass, M_{acc} , in **Figure 7c**. clearly shows that
 482 RefractoryOC and VolatileOC tend to reduce γ as they become a larger fraction of the
 483 aerosol mass. This confirms that the relationship found for surface observations
 484 downwind of the east coast and our data in Asian outflow [Quinn *et al.*, 2005] also
 485 applies generally to the North American aerosol sampled during INTEX-A.
 486

487 6.0 Spectral Dependence of Absorption and Refractory OC

488
 489 As noted in the introduction, the light scattering and light absorbing properties of
 490 the aerosol and their wavelength dependence are linked to size and composition. The
 491 wavelength dependence of absorption (absorption Angström, α_{ap}) and scattering
 492 (scattering Angström, α_{sp}) are defined as:

493

$$494 \alpha_{\text{ap}} = \frac{\ln\left(\frac{\sigma_{\text{ap},470}}{\sigma_{\text{ap},660}}\right)}{\ln\left(\frac{660}{470}\right)} \quad \text{and} \quad \alpha_{\text{sp}} = \frac{\ln\left(\frac{\sigma_{\text{sp},450}}{\sigma_{\text{sp},700}}\right)}{\ln\left(\frac{700}{450}\right)} \quad \text{Eqn. 2 a,b}$$

495
 496 **Figure 8** shows the result of plotting absorption measured at 470nm against
 497 absorption at 660nm for all the data discussed here. Clearly the BB plumes show an
 498 enhanced absorption in the shorter wavelengths consistent with other measurements on
 499 BB aerosol [Kirchstetter *et al.*, 2004]. Histograms of this wavelength dependence for
 500 these plumes are also shown for P and BB. The absorption Angström peaks at about 0.75
 501 and is lower than the nominal 1.0 expected for common BC but is in the range of values
 502 (0.7 – 1.1) observed elsewhere for pollution aerosol [Kirchstetter *et al.*, 2004]. The
 503 absorption Angström for BB peaks near 1.7 and is consistent with the range of 1.2 – 2.2
 504 reported by the same author for African biomass smoke. The non-plume cases clearly
 505 show a greater similarity to the P plume wavelength dependence, as was evident in the
 506 mass fraction histograms (**Figure 4**).

507 As discussed in the introduction, this steeper wavelength dependence is related to
 508 the enhanced organic fraction in the BB aerosol (**Figure 4**). We can now ask whether it is
 509 the volatile or refractory organic carbon species that is most responsible for the steeper
 510 wavelength dependence in either plume type. This is evident in **Figure 9a** where

511 RefractoryOC/TotalOC is plotted against the absorption Angström. As the RefractoryOC
512 fraction of total OC increases the absorption Angström increases indicating a stronger
513 wavelength dependence for this component. As VolatileOC/TotalOC is just (1 –
514 RefractoryOC/TotalOC) the VolatileOC fraction actually would yield a weaker
515 wavelength dependence (not shown). This confirms RefractoryOC is primarily
516 responsible for the enhanced short wave absorption in BB (largest absorption Angström).

517 **7.0 Discussion**

518

519 The above data indicates that our combined measurements of size-resolved
520 aerosol thermal volatility, estimated BC mass from light absorption and ionic mass
521 provides estimates of VolatileOC and RefractoryOC. Together these OC components
522 were shown to compromise about 30% ±10% of pollution plumes and about 80% ±10%
523 of biomass burning plumes over North America during INTEX-A. VolatileOC was
524 shown to be related to WSOC while RefractoryOC accounts for the enhanced absorption
525 at shorter wavelengths. Both OC components were shown to lead to a suppression of
526 aerosol growth under increasing humidity as their mass fractions increased.

527 As mentioned in the introduction, HULIS in biomass burning has been recently
528 identified as contributing to enhanced light absorption at shorter wavelengths. Our data
529 reveals that RefractoryOC dominates this enhanced absorption over North America.
530 Hence, the absorption properties of the RefractoryOC component are those that are
531 important to determine. Because the mass of RefractoryOC is distributed over a well
532 defined size range (**Figure 3**), it is useful to establish the mass absorption efficiency
533 (MAE) of this component. A known MAE allows models to calculate the absorption
534 from the relevant OC mass present in the models.

535 We estimate the MAE of RefractoryOC by recognizing that the absorption at
536 660nm is dominated by BC and that OC generally contributes a negligible amount at this
537 wavelength [*Hoffer et al., 2005; Kirchstetter et al., 2004*]. We can then account for the
538 contribution of the BC component measured at shorter wavelengths by applying the
539 typical wavelength dependence $\lambda^{-0.8}$ found here (**Figure 8 bottom**) for the P plumes
540 dominated by absorbing BC. If we assume the BC component present in BB plumes
541 absorbs with this same wavelength dependence then the BC contribution can be estimated
542 for all wavelengths. When subtracted from the total BB absorption measured at 530 nm
543 and 470 nm this leaves the absorption enhancement ($\Delta\sigma_{ap}$). Based upon **Figure 9a** we
544 assume here that this is due to RefractoryOC in BB alone.

545 The resulting $\Delta\sigma_{ap}$ data for BB plumes on INTEX-A are shown vs. RefractoryOC
546 mass in **Figure 9b**. The linear slope for $\Delta\sigma_{ap}$ vs. RefractoryOC mass defines the MAE at
547 each wavelength. At 470 nm the slope yields a value of $0.51 \text{ m}^2\text{g}^{-1}$ while at 530 nm it
548 drops to $0.16 \text{ m}^2\text{g}^{-1}$. If we had assumed a λ^{-1} dependence for the small particle limit for
549 high absorbing material for BC absorption in BB aerosol we would get MAE values of
550 $0.47 \text{ m}^2\text{g}^{-1}$ (470nm) and $0.1 \text{ m}^2\text{g}^{-1}$ (530nm). While these values appear small compared to
551 the MAE for BC, the refractory OC present in BB aerosol is about ten times the mass of
552 BC (**Figure 4**) making RefractoryOC a significant absorber (about 15% of BC) at 530nm
553 and with absorption similar to BC at 450nm. These MAE values are based upon the 3- λ
554 PSAP absorption, OPC volumes and the assumed density of 1.8 g cm^{-3} . While the latter
555 are reasonable we expect their uncertainty could possibly alter these estimates by as much

556 as 20%. If the 3- λ PSAP measured absorption is as much as 25% low (as mentioned
557 earlier) then these MAE values will be a lower limit. We also note that our Refractory
558 OC is operationally defined based upon the 400° temperature separation discussed earlier.
559 Hence, the actual absorbing OC component may have a mass somewhat larger or smaller
560 than we estimate here depending upon its exact thermal behavior near 400° as well as
561 possible volatility of non-absorbing components near this temperature. Furthermore,
562 although we have treated RefractoryOC here as a separable component from BC, it is
563 likely to be a primary emission that is absorbing and internally mixed with the BC.
564 Hence, it may act to enhance BC absorption and/or “shield” some of the encapsulated BC
565 from the full intensity of incident radiation [Fuller *et al.*, 1999]. Understanding such
566 effects will require careful modeling of the effective absorption of the combined mixture.

567 The wavelength dependence of scattering is closely coupled to the size
568 distribution. The examples of BB and P plumes shown in **Figure 2** reveal a difference in
569 size for these plume types with the BB plume being larger. Consequently, if this is a
570 typical feature of these sources, then these plume types should be distinguishable not only
571 by their absorption Angström coefficient but also their scattering Angström coefficient.
572 This is evident in **Figure 10a** where these coefficients are plotted against each other and
573 show a clustering of the BB and P cases. The limited number of cases when the
574 absorption Angstrom is below 0 is in part due to low absorption values (a differential
575 measurement) and the influence of variability in pressure and RH, often worse during
576 profiles. This clustering makes sense in terms of the larger size (smaller scattering
577 Angström) and enhanced shortwave absorption (larger absorption Angström) of BB
578 plumes relative to P. However, a portion of the data identified as P data from trace gas
579 assessment appear to be exceptions and are circled in the figure. In **Figure 10b**, the same
580 data is color coded by the measured Ca^{2+} to accumulation mode mass (Macc) volume
581 whenever Ca^{2+} data was available. These points are clearly enhanced in Ca and all
582 occurred during Flight 18 over the Gulf of Mexico in an air mass coming from the south.
583 Enhanced coarse particles and coarse scattering (not shown) and elevated Ca^{2+} indicate the
584 presence of a mixture of mineral dust and pollution. Dust lowers the scattering Angström
585 [Clarke *et al.*, 2004] and has enhanced absorption at short wavelengths that exceed those
586 of RefractoryOC [Patterson, 1981]. A greater dust contribution would lower the
587 scattering Angström and enhance the Absorption Angström even more. Hence, the
588 observed behavior of the circled points makes sense and demonstrates the value of these
589 optical spectral signatures for identifying aerosol types and their mixtures. In principle,
590 such measurements through the atmospheric column could partition the relative
591 contribution of mixed plume types. We also note the indication of a gradient in the
592 absorption Angström within the dense P cluster linked to the Ca/Macc ratio that will be
593 the subject of a future paper exploring this approach.

594 The spectral measurements of absorption and scattering are related to the
595 underlying physiochemistry of the aerosol, as is true of the humidity dependent response
596 of the aerosol light scattering expressed as γ . When the Angström coefficients for
597 absorption and scattering are plotted vs. γ they exhibit a decreasing and increasing
598 behavior respectively (**Figure 10c**). Hence, the difference in the value of these two
599 Angström coefficients could provide an estimate of γ . If this relationship is common and
600 if these parameters could be reliably sensed remotely then the effective γ might also be

601 retrieved although mixed properties over the ambient column could make this difficult to
602 apply [Shinozuka *et al.*, submitted 2006].

603 The above considerations of these optical properties, their link to aerosol
604 physiochemistry and the associated $f(\text{RH})$ or γ also impacts the values of the aerosol
605 single scattering albedo, SSA. This is often reported for the measured dry aerosol
606 although it is the ambient “wet” aerosol that is remotely sensed and most important for
607 modeling atmospheric radiative effects. In this data we have seen systematic differences
608 in size, composition and humidity response for the BB and P plumes. Here we show how
609 these systematic differences in size and $f(\text{RH})$ can lead to a reduced variability in SSA
610 under ambient conditions. We examine SSA dependencies here under the assumption
611 that they are little affected by any modification to absorbing properties by water uptake
612 [Nessler *et al.*, 2004].

613 The mean accumulation mode aerosol size can be expressed as a size parameter
614 defined by the ratio of measured OPC accumulation mode volume (V_{acc}) to
615 accumulation mode number (N_{acc}). The larger the integral volume per integral number
616 of particles in the accumulation mode, such as those in **Figure 2**, then the larger the mean
617 diameter becomes. **Figure 11a** shows the dry SSA vs. the aerosol absorption (530nm)
618 and color coded with this size parameter. A strong “rainbow” effect reveals that dry SSA
619 depends strongly on size and not just absorption. The horizontal spread of data points for
620 BB plumes with larger size (blue) shows that SSA is constant for a large range in
621 absorption. This implies that scattering and absorption scale together in these BB plumes
622 while effective particle size remains the same.

623 In **Figure 11b** we plot dry SSA against the absorption per unit mass of the
624 accumulation mode. This “collapses” the BB data and “tightens” the spread of the data
625 while preserving and enhancing the “rainbow” effect that reveals the size dependence of
626 dry SSA. For a given color (ie. effective size) the increase in absorption per unit mass
627 results in the expected reduction in SSA with the strongest dependency (steepest slope)
628 evident for the smallest sizes (red). The dependency of SSA on size is clear if you
629 consider the range of colors for particles with a particular absorption per mass (say 0.5 m^2
630 g^{-1}). These exhibit a range of dry SSA from about 0.91 to 0.97 as their $V_{\text{acc}}/N_{\text{acc}}$, is
631 seen to increase by a factor of about 4 ($0.002 \rightarrow 0.01$). This implies an effective diameter
632 increase of $4^{1/3}$ or about 1.6. This is consistent with **Figure 2** that shows a volumetric
633 mean diameter of $0.45 \mu\text{m}$ for the BB case compared to $0.30 \mu\text{m}$ for the P case, a factor
634 of 1.5. This shift to higher SSA is evident when the accumulation mode SSA is written as
635 $(1+\text{MAE}/\text{MSE})^{-1}$ [Clarke *et al.*, 2004] and the aerosol mass scattering efficiency, MSE,
636 changes more rapidly with size than the mass absorption efficiency, MAE. Because the
637 scattering Angström exponent is more conventionally measured and can be sensed
638 remotely as a size indicator (lower values indicating larger sizes) we show the same data
639 color-coded with this parameter in **Figure 11c**. The scattering Angström exponent is not
640 as directly linked to the accumulation mode size distribution as the parameter $V_{\text{acc}}/N_{\text{acc}}$
641 but shows the same range and rainbow behavior as **Figure 11b**.

642 All of the plots in **Figure 11a,b,c** are for the dry aerosol. However, we are more
643 interested in the behavior of SSA under ambient conditions, $\text{SSA}_{\text{ambient}}$. This is shown in
644 **Figure 11d** where we have recalculated the scattering at ambient RH based upon fits (γ)
645 to continuously measured $f(\text{RH})$ on the DC-8. The data have here been color-coded with
646 the P, BB and non-plume “background” code used elsewhere. This figure also shows that

647 much of the spread in the SSA data is reduced. If we look at the variation in SSA_{ambient}
648 again at $0.5 \text{ m}^2 \text{ g}^{-1}$ it is now 0.93 to 0.97, about a factor of two reduction in variability for
649 a given absorption per unit mass. Hence, for a given mass and a given absorption, the
650 uncertainty in SSA_{ambient} is about a factor of two less than dry SSA.

651 This behavior and the greater increase in SSA_{ambient} for smaller sizes with lower
652 dry SSA can be a consequence of several factors. First, for a given composition or
653 humidity dependent diameter change, $g(\text{RH})$, smaller accumulation mode sizes have
654 significantly higher $f(\text{RH})$ or γ [Howell *et al.*, 2006b]. This results in a greater relative
655 scattering increase for the smaller sizes. Second, the largest accumulation mode aerosol
656 in INTEX-A were measured in the BB plumes (**Figure 2**) having the largest OC fraction
657 (**Figure 3**) and the lowest $f(\text{RH})$ or γ . These considerations imply that, for a given
658 absorption per unit mass, SSA_{ambient} increases more relative to SSA_{dry} for the smallest
659 sizes with the largest ion fractions and changes least for the largest sizes with the lowest
660 ion fraction.

661 Assuming these INTEX-A measurements are generally representative of aerosol
662 over North America, this observation is promising for models that use MSE, MAE,
663 aerosol mass and relative humidity to calculate ambient aerosol extinction and SSA.
664 **Figure 11d** suggests the range of SSA_{ambient} simulated by a model can be constrained by
665 the regressions indicated for P and BB plumes measured. Models that include the
666 absorbing aerosol component and the accumulation mode mass should obtain typical
667 ambient SSA values indicated in the plot for the regressions on the P and BB plumes.
668 The slopes for these fits are not sensitive over this SSA range to the previously mentioned
669 uncertainty in absorption values. The results indicate that, for the same absorption per
670 unit mass, P plumes will have a somewhat lower SSA_{ambient} values than BB plumes.

671

672 **Conclusion**

673

674 Thermal volatility of dry size distributions was used in conjunction with
675 concurrent measured ion concentrations, BC mass estimated from light absorption and
676 realistic density values to provide estimates of the OC mass concentration by difference.
677 Heating to 400°C is effective at separating out a more volatile and refractory organic
678 component. The VolatileOC component's relation to CO was shown to be similar to that
679 for water soluble OC (WSOC) measured on the NOAA P3_B during the same campaign,
680 indicating that these are likely dominated by the same OC species. On the other hand,
681 only RefractoryOC exhibited the short wavelength enhancement in absorption
682 characteristic of biomass burning aerosol.

683 This rapid in-situ thermal technique appears capable of characterizing the OC
684 mass of the aerosol related fundamental physio-chemical properties. This was of clear
685 value to INTEX-A where OC was a significant contribution to aerosol mass but no
686 aerosol OC measurements were available on the DC-8. Statistically significant
687 differences in mass fractions of ions, VolatileOC, RefractoryOC, and BC were obtained
688 for biomass (BB) and pollution plumes (P) identified by trace gases. These differences
689 also expressed themselves as less growth under increasing humidity for BB plumes due to
690 their larger OC mass fractions. Comparison of plume features with data not exhibiting
691 plume structure or concentrations (regional background) showed that the latter was more

692 strongly influenced by P and BB emissions below about 2 km. Above that altitude BB
693 plumes had a greater contribution but their occurrence is both seasonal and episodic.

694 Multiwavelength measurements of absorption and scattering coefficients proved
695 effective at distinguishing BB, P and dust influenced plumes. The absorption Angström
696 coefficient (470-660 nm) for BB plumes had a value centered about 1.7 while that of P
697 plumes was near 0.75. Enhanced shortwave absorption over that expected for BC in BB
698 plumes was a function of RefractoryOC. The slope of this dependency yielded a mass
699 absorption efficiency, MAE, of this component of about $0.51 \text{ m}^2\text{g}^{-1}$ at 470 nm and
700 dropping to $0.16 \text{ m}^2\text{g}^{-1}$ at 530nm with an estimated uncertainty of about 20%. For these
701 biomass burning aerosols the fraction of total absorption due to RefractoryOC was
702 comparable in magnitude to BC at 470 nm but on the order of 10% that of BC at 530 nm.

703 The humidity dependence of light scattering expressed as $f(\text{RH})$ or γ was shown
704 to depend upon composition and size in ways that were linked to spectral optical
705 properties, including the OC component. The difference in the scattering and absorption
706 Angström exponents increased with $f(\text{RH})$, suggest a possible way to estimate $f(\text{RH})$ with
707 remote spectral measurements. Smaller but more absorbing aerosol in pollution were
708 found to exhibit the largest values for $f(\text{RH})$ while the largest biomass burning aerosol
709 exhibited the lowest $f(\text{RH})$. Under ambient RH conditions these properties tended to
710 reduce variability in SSA at ambient RH for a given absorption per unit mass and
711 regressions for P and BB plumes may provide useful constraints upon model values for
712 ambient SSA.

713

714 **Acknowledgements:** We would like to acknowledge support of part of our team through
715 NASA grant NNG04GB39G for this work. We also thank the NASA DC-8 team at
716 NASA's Dryden Flight Research Center, California for their mission support. We extend
717 a special thanks to Dr. David Covert (U. of Washington) for loan of the 3- λ PSAP for this
718 study. We also thank Dr. Glen Sachse (NASA Langley Research Center) for the CO data
719 used here. This is SOEST contribution number #####.

Figure 2. Thermograms of evolved CO₂ in oxygen as adapted from references in text. **a)** thermograms the acetone soluble and acetone insoluble component components for BB sample (African savanna) and apparent absorbing BC peak highlighted near 450C (Kirschtetter, 2001, TK). **b)** same only for tunnel pollution dominated by diesel with BC peak near 520C. **c)** thermogram of pollution/biomass plume from Indian Ocean with concurrent total CO₂ (grey) and CO₂ for the absorption peak (BC) highlighted near 490C (Mayol-Bracero, 2002a, MB). These reveal that OC can evolve at many temperatures including those associated with BC (a) and that the temperature where absorbing BC can evolve can vary with sample type.

Figure 6. a) VolatileOC vs. CO for P, BB and non-plume (background) data converted to unit density by dividing by 1.3 to account for the estimated volatile WSOC non-carbon mass. The regression line for pollution cases only and biomass burning cases (stars) are taken from Sullivan et al. (submitted, see text). The line describes their WSOC (given as $\mu\text{g C m}^{-3}$ for an assumed density of 1.0 g cm^{-3}). Scatter below the zero line (negative VolatileOC) arises at low concentration due to subtraction of distributions (heated and unheated) that are a few minutes apart and provide a measure of uncertainty in this approach. Otherwise all features of the data (scatter, more data above line for higher CO) are the same as seen in the Sullivan et al. WSOC data. **b)** The Refractory OC ($\rho = 1.3 \text{ g cm}^{-3}$, this paper) vs. CO shows distinct slopes for P and BB cases.
